SIXTEEN YEARS OF DERMATOMYCOSIS CAUSED BY *Candida* spp. IN THE METROPOLITAN AREA OF PORTO ALEGRE, SOUTHERN BRAZIL

Daiane HEIDRICH(1), Cheila Denise Ottonelli STOPIGLIA(1,2), Cibele Massotti MAGAGNIN(1), Tatiane Caroline DABOIT(1,3), Gerson VETTORATO(4), Taís Guarienti AMARO(4) & Maria Lúcia SCROFERNEKER(1,5)

SUMMARY

The yeasts of the genus *Candida* infect skin, nails, and mucous membranes of the gastrointestinal and the genitourinary tract. The aim of this study was to determine the prevalence of dermatomycoses caused by *Candida* spp., and their etiological aspects in the metropolitan area of *Porto Alegre*, Brazil. A retrospective study with data obtained from tertiary hospital patients, from 1996 to 2011, was performed. The analyzed parameters were date, age, gender, ethnicity, anatomical region of lesions, and the direct examination results. For all the statistical analyses, $\alpha = 0.05$ was considered. Among positive results in the direct mycological examination, 12.5% of the total of 4,815 cases were positive for *Candida* spp. The angular coefficient (B) was -0.7%/ year, showing a decrease over the years. The genus *Candida* was more prevalent in women (15.9% of women versus 5.84% of men), and in addition, women were older than men (54 versus 47 years old, respectively). There was no difference between ethnic groups. The nails were more affected than the skin, with 80.37% of the infections in the nails (72.9% in fingernails and 7.47% in toenails). Our study corroborates the literature regarding the preference for gender, age, and place of injury. Moreover, we found a decrease in infection over the studied period.

KEYWORDS: Epidemiology; Dermatology; *Candida*.

INTRODUCTION

Cutaneous candidiasis is a dermatomycosis caused by the genus *Candida*, especially *C. albicans*, which infects skin, nails, and mucous membranes of the gastrointestinal and the genitourinary tract¹⁻⁴. This yeast is part of the normal skin microbiome in healthy individuals and only causes infection when the normal commensal balance is disturbed⁴.

Most infections caused by *Candida* spp. tend to appear in intertriginous areas with moist conditions created by maceration and occlusion⁵. In these sites, the lesions are moist with prominent borders⁶. Treatment involves the use of topical antifungals such as ketoconazole cream or nystatin powder or cream, and in several cases oral treatment with ketoconazole or fluconazole are required⁴. *Candida* onychomycosis cause periungual lesions and inflammation (paronychia or perionix), onycholysis, or it may colonize other injuries^{2,7-9}. Oral treatment with itraconazole or fluconazole is commonly used⁴. It has been reported that *Candida* species are the main causes of onychomycosis¹⁰⁻¹³, representing more than 90% of onychomycosis caused by yeasts, and their prevalence worldwide is up to 29%¹⁴. In a study conducted in *Rio Grande do Sul*

State, Brazil, from 1988 to 1997, the genus *Candida* accounted for 28.8% of onychomycosis¹⁵. Therefore, due to its high frequency in clinical practice, the aim of this study is to determine the prevalence of dermatomycoses caused by *Candida* spp. and their etiological aspects in the metropolitan area of *Porto Alegre*, *Rio Grande do Sul*, Brazil.

MATERIAL AND METHODS

Patients

A retrospective study was carried out using data from the direct mycological examination of all patients in attendance at the Department of Dermatology of the *Complexo Hospitalar Santa Casa de Porto Alegre*, in the south of Brazil, from January 1996 to December 2011. The research project was approved by the Hospital Ethics Committee under the protocol number 3484/11.

Diagnostics

Skin and nail samples were collected by means of scraping injured surfaces with microscope slides and sterile curettes. The material was

clarified with potassium hydroxide at 20% and examined under optical microscope. The test for *Candida* spp. was considered positive when the characteristic blastoconidia and pseudohyphae of this genus were found^{2,16}. The presence of pseudohyphae in the material indicates infection, not colonization, by the genus *Candida*².

Collected data

The analyzed parameters were date, age, gender, ethnicity, anatomical region of lesion, and the direct examination results. Then, according to the Brazilian Institute of Geography and Statistics (IBGE), white, brown (mixed ethnicity), and black ethnicity classifications were taken into consideration. The distribution of ethnic groups, called sample proportion, included all the subjects who underwent direct examination during the study period.

The anatomical areas with lesions were scalp, face, oral mucosa, trunk, arms, legs, groin and genital areas, feet, hands, toenails, and fingernails.

Statistical analyses

The statistical tests performed (considering $\alpha = 0.05$), and the programs used for each specific analysis of the study were:

For the evaluation of the prevalence tendency of yeasts belonging to the genus *Candida* over the years, a simple linear regression was performed with the SPSS program, version 18, using the x and y coordinates as described: $x = \text{year}$; $y = (\text{number of yeasts belonging to the genus } \textit{Candida} \text{ in a year} / \text{total number of positive fungi tests in a year}) \times 100$.

For comparison of the prevalence of the genus *Candida* between the genders, the Pearson's Chi-square test was performed with the R Program, version 13.2. In this analysis, 100% represented the total number of cases in each gender that were positive for mycological direct examinations, regardless of the fungus.

For comparison of the ages of patients infected by yeasts belonging to the genus *Candida* spp., between genders, the Mann-Whitney U test was performed with the SPSS program, version 18.

For comparison of the ethnic proportion of cases affected by *Candida* spp. with the sample proportion, the Chi-square test corrected by Bonferroni was performed with the WinPEPI program, version 11.25.

For each of the analysis, cases with missing values in the variables to be analyzed were excluded.

RESULTS

Of the 71,463 cases examined, 38,520 (53.9%) were positive for fungi, and of these, 12.5% (4,815) were positive for *Candida* spp. The angular coefficient (B) was -0.7%/ year, showing a decrease over the years when compared with other direct examination results ($p < 0.001$). The genus *Candida* was more prevalent in women (15.9% of women versus 5.84% of men), and in addition, affected women were older than men (54 versus 47 years, respectively) (Table 1). Figure 1 shows the percentages of male and female patients infected by *Candida* spp. In the

different age groups, it is possible to deduce that younger men are more affected by these yeasts than women of the same age.

Table 1

Age and prevalence of dermatomycosis due *Candida* spp. between genders in the metropolitan area of Porto Alegre, Brazil (1996-2011)

	Gender		p
	Male	Female	
Median Age (quartis 25/75)	47 (32/60)	54 (43/64)	<0.01
number of cases	722	3866	
Infection (%)	5.84	15.9	<0.01
number of cases	772	4039	
number of positive direct examination for any fungi	13223	25411	

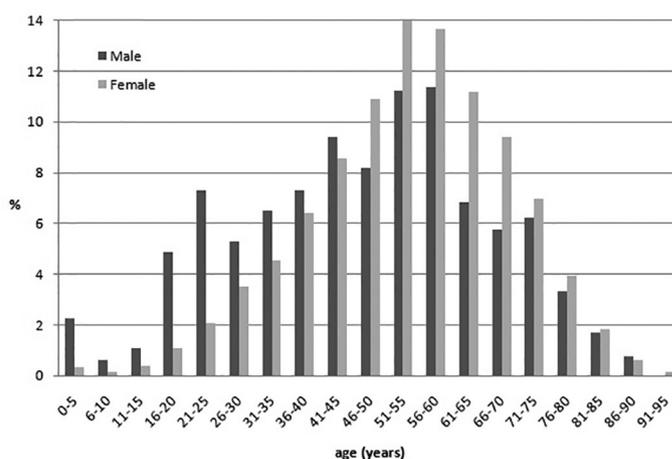

Fig. 1 - Age prevalence of male and female patients infected by *Candida* spp. in the metropolitan area of Porto Alegre, Brazil (1996-2011).

There was no significant difference between ethnic groups (Fig. 2).

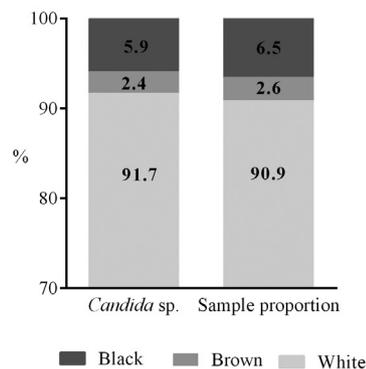

Fig. 2 - Ethnic proportion of infections caused by the *Candida* genus in comparison with the sample proportion (%) in the metropolitan area of Porto Alegre, Brazil (1996-2011). $p = 0.196$. Number of cases = 4,628. Ethnic sample proportion = all patients submitted to the mycological direct examination (71,463).

The nails were more affected (80.4%) by the *Candida* genus than the skin, showing 72.9% of the infections in fingernails and 7.47% in toenails (Fig. 3).

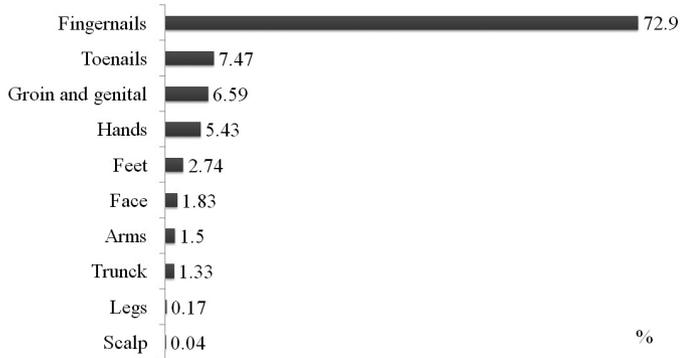

Fig. 3 - Prevalence of *Candida* spp. in anatomical sites of lesions (%) in the metropolitan area of Porto Alegre, Brazil (1996-2011). Number of cases = 4,809

DISCUSSION

Dermatomycoses are fungal infections that affect skin, hair, and nails and are caused by various etiologic agents. The fungi that most commonly cause cutaneous mycoses are dermatophytes and yeasts of the genera *Candida* and *Malassezia*¹⁷⁻¹⁹. Yeasts found in nails cited in the literature belong to the genera *Candida*, *Trichosporon*, *Malassezia*, *Geotrichum*, and *Rhodotorula*²⁰⁻²². However, up to 90% of the superficial mycosis caused by yeasts have the genus *Candida* as the etiologic agent^{14,23}.

To our knowledge, this is the second study with the largest number of dermatomycoses cases caused by *Candida* spp., with 4,815 cases. The other study analyzed 6,227 cases from Croatia and observed an increase in infections caused by *Candida* spp. during the study period (1999-2008)²⁴. On the contrary, we found a decrease over the years in infections caused by this genus when compared with the other results of direct examination.

For this study, only results of the mycological direct examination were used because many patients lived far from the hospital and had low incomes, so that they would not be able to return for a second appointment in which the results of the fungal cultures would be available and the patients could receive the optimal treatment for mycosis. This is the reason why the doctors of the Hospital prescribe treatment according to the result of mycological direct examination.

Among the fungal structures found upon the direct examination, 12.5% were consistent with *Candida* yeasts. Discrepant results were obtained in other studies in which this genus was found in 16.2 to 71.9% of dermatomycoses, considering the fungal culture results²⁴⁻²⁶. In those studies, the results of the fungal culture were used in the surveys, whereas, in our study, data came from the results of the direct examination, a fact that may explain the differences found in our study. Furthermore, many tests were performed in the toenails during the study period (data not shown), probably overestimating the percentage of other fungi, such as dermatophytes, which have a closer relationship with the lesion site when compared with the genus *Candida*. The fingernails are the most commonly affected place by this yeast^{1,9,15,24,25,27-32}, as also observed in this study.

Regarding the gender, 83.9% of those affected by *Candida* spp. were female, which is in accordance with many Brazilian studies and those from other countries that have reported higher prevalences of dermatomycoses caused by *Candida* species in women, especially onychomycosis^{9,18,27-29,32-34}. Some reasons for this fact are presented by the authors. Women are usually more concerned about their appearance and health than men¹⁸; the continued immersion of women's fingers in water, leading to macerated cuticles which can be a gateway for infections^{4,27,35}; the maceration of periungual tissue caused by the use of manicure tools that were not properly disinfected can promote cross-infection among people who use this service^{18,36}; and the contact with *Candida* organisms that reside in the intestine or vagina^{35,37}. The last three reasons also explain why the yeast attacks fingernails more often than other parts of the body. Fingernail infection is considered to have an occupational nature, especially in professions that require a frequent contact with water¹⁸. The relationship between *Candida* spp. and water is so strong that VENUGOPAL *et al.*³⁸ pointed out that the high prevalence of *Candida* genus found in toenails of patients was probably related to the Muslim religious practice of washing the feet five times a day.

When comparing men and women in relation to age, there was a statistical difference, namely, the women's age was higher than the men's. We also compared the proportion of ethnic groups affected, showing that there is no relationship between infection by *Candida* spp. and ethnicity. We did not find these analyses in other studies in the literature.

The median age was 53 years, corroborating the literature data^{18,27}, and there is a low frequency of dermatomycoses among patients from both extremes of the age range (the youngest and the oldest patients). The low number of cases among children and adolescents is explained by several authors who affirm that onychomycosis, which constitutes the vast majority of cases and lesions caused by *Candida* spp., is rare before puberty, and some reasons for this fact are that at younger ages people have a faster rate of nail growth, making fungal infections at these sites more difficult³⁹, and that onychomycosis caused by *Candida* spp. in children has been seen in fingernails only due to finger sucking habits⁴⁰. Some investigators have claimed that children below the age of three are more vulnerable to onychomycosis caused by *Candida* species other than *C. albicans* such as *C. glabrata*^{2,11,41}. In elderly people, the low incidence of nail infection may be due to the fact that these patients search for a specific medical appointment only when the nail is too debilitated or due to other type of skin problems. Thus, the diagnosis of onychomycosis is usually a secondary diagnosis among elderly patients¹⁸. Health care providers should be aware that chronic and recurrent episodes of candidiasis in the elderly can be an indicator of an underlying condition such as diabetes, malignancy, vitamin deficiency, or malnutrition, and that appropriate investigation should be performed⁴.

In conclusion, our study corroborates the data in the literature regarding the higher number of females with dermatomycoses caused by the *Candida* genus; the fingernails are the most frequent site of infection; and the highest prevalence was observed in adulthood. Furthermore, we found that there is no relationship between this yeast and ethnicity, that women infected by *Candida* spp. are older than men, and that there was a decrease in dermatomycoses caused by *Candida* spp. over the sixteen years of study. Therefore, the continuation of long-term epidemiological studies in the metropolitan area of Porto Alegre, Brazil, is needed to

monitor the increase or decrease in the frequency of dermatomycoses related to *Candida* genus.
